Summary

Polymorphism

Is a paradigm that allows related objects belonging to different concrete classes to be treated as uniform supertype or interface objects within client code. Rather than relying on conditional logic or runtime type checks to execute type specific behavior. While it defers exact program execution details to runtime, it dramatically cleans up client code, reduce maintenance complexity, and improves software extensibility.

Interfaces

Serves as a contract or blueprint that explicitly declares a set of public behaviors that implementing classes must fulfill without prescribing how those behaviors are executed. Them allow developers to decouple client code from concrete implementations by establishing common types, though abstract classes cannot be instantiated. By referencing interface or abstract superclass types rather than specific concrete classes, systems become highly modular and extensible. Enforce consistent method signatures across different components ensuring that any conforming class can seamlessly plug into system workflows while keeping internal data fields encapsulated.

Abstraction.

Process of focussing on essential details relevant to a specific context while suppressing or forgetting irrelevant information to reduce complexity and define clear boundaries. Creates an explicit contract by exposing only the necessary public features, that other components depends on, while keeping internal implementatios private. Adhering to strong abstraction principles improves overall code maintainability, testability and reusability
